Abstract

The concept of compression of the rostral ventrolateral medulla as a cause for hypertension is gaining more and more interest. This report is about a 36-year-old male with a three years history of hypertension who presented with a posterior fossa mass suggestive of a hemangioblastoma. Laboratory and imaging studies ruled out the presence of von Hippel-Lindau disease and/or concomitant pheochromocytoma. Post-surgical blood pressure monitoring revealed a 40 mmHg decline in blood pressure. It could be hypothesized that alleviation the compressive effect of the tumour on the rostral ventrolateral medulla as proposed by previous studies could be a contributing factor.

Introduction

Hemangioblastomas (Grade I in World Health Organization classification of brain tumors) constitute around 2–3% of all primary nervous system tumors and although they can occur at all sites from the cerebral cortex to peripheral nerves, are most commonly found in the cerebellar hemispheres [1,2]. Presentations are related to mass effects on the neural structures and raised intracranial pressure. Various abnormalities such as retinal hemangioblastomas, renal and pancreatic cysts, renal carcinoma, pheochromocytoma, pancreatic islet cell tumors, endolymphatic sac tumors, and papillary cystadenoma of the epididymis are reported in 25% of hemangioblastomas as a part of von Hippel-Lindau disease (VHL) [1,3]. However, systemic hypertension not associated with

pheochromocytomas in sporadic cases of hemangioblastoma is a rarity. The intriguing association between arterial hypertension and posterior fossa tumors and its amelioration after total surgical removal has been touched in this case.

Case presentation

A 36-year-old Iranian male with Caucasian ethnicity referred to the emergency department of our institute with a chief complaint of severe suboccipital headache, vomiting and frequent drop attacks. He had arterial hypertension for 3 years and was taking atenolol 50 mg/day. Family history was negative for secondary causes of arterial hypertension including adrenal disease. Physical examination revealed blood pressure of 180/100 mmHg, bilateral papilledema and truncal ataxia with gaze-

dependent horizontal nystagmus. Lab tests showed polycythemia (Hemoglobin = 18 g/dL). Contrast enhanced brain MRI showed a round extra-axial heterogeneous densely enhanced 4 × 4 cm mass with irregular margins. It was located in the left cerebellar hemisphere, posterolaterally obliterating the fourth ventricle, causing non-communicating hydrocephalus. The mass encroached onto the cavity of the fourth ventricle anterolaterally, abutting the right half of the brainstem (Figure 1). Magnetic resonance imaging of the whole spine was negative for spinal lesions. Regarding severe headache and vomiting due to the non-communicating hydrocephalus, a ventriculoperitoneal shunt was inserted on an emergency basis, postponing tumor removal for further evaluation. However, the patient remained hypertensive despite

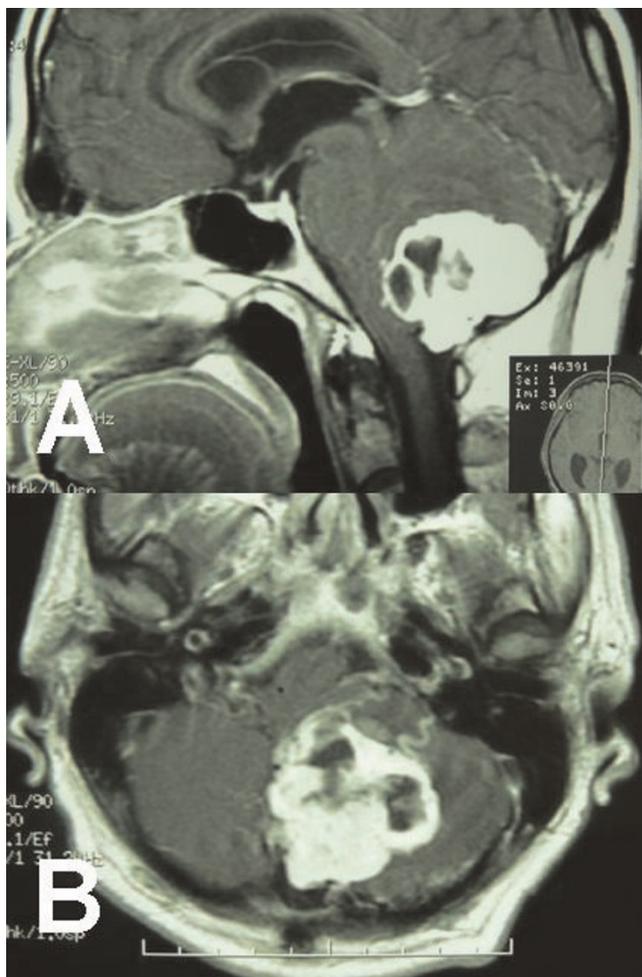

Figure 1. (A) and (B) Sagittal and axial T1-weighted magnetic resonance images of brain after contrast injection showing a solid-cystic densely enhancing mass in the left cerebellar hemisphere with compressive effect upon the fourth ventricle causing obstructive hydrocephalus.

Figure 2. Computed tomographic angiogram of brain showing a highly vascular mass supplied by multiple tortuous feeders originating from cerebellar cortex as well as postero-inferior cerebellar artery.

alleviated symptoms of raised intracranial pressure. Computed tomographic (CT) angiography (with 3D reconstruction) revealed a highly vascular lesion irrigated by hypertrophied right posterior inferior cerebellar artery (PICA) (Figure 2). Abdominal CT scan showed 2 simple cortical cysts in the right kidney. Urinary 24-hour metanephrine and vanillylmandelic acid (VMA) excretion were found to be within normal limits. Ophthalmology consult did not reveal retinal vascular lesions.

A midline posterior fossa craniectomy was performed. Following durotomy, the mass appeared as a reddish lobulated tumor with multiple feeders from cerebellar cortex and the bridging PICA which were coagulated and divided. Not surpassing the surrounding gliotic border, the tumor was totally resected. Post-operative period was uneventful and the obtained MRI revealed no residual tumor (Figure 3). Surprisingly, blood pressure showed a drastic decline of about 40 mmHg and the patient remained normotensive for the next 6 months of follow-up, needing no anti-hypertensive medication. The pathological examination confirmed the diagnosis of hemangioblastoma. The specimen stained positive for Glial Fibrillary Acidic Protein (scattered), S100 (scattered), MIB1 and CD34 and negative for Cytokeratin, epithelial membrane antigen (EMA), Neuron Specific Enolase (NSE) and neuropeptide Y.

Discussion

Secondary hypertension may be caused by a myriad of secretory disorders, including some tumors such as pheochromocytoma and aldosterone-secreting masses.

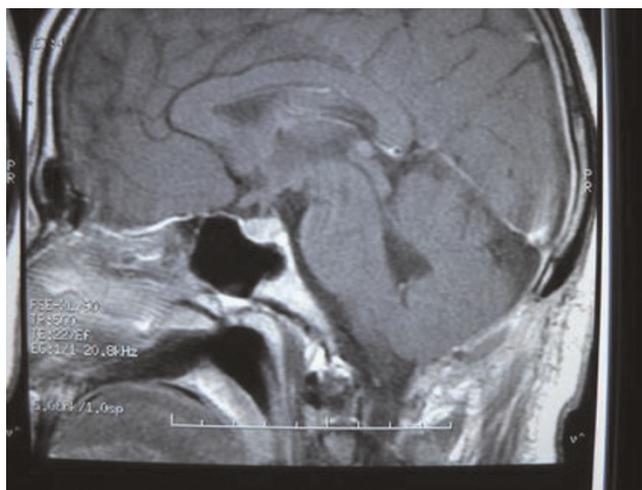

Figure 3. Post-operative magnetic resonance image of brain revealing no residual tumor and restoration of the 4th ventricular contour.

However, not all these hypertensive states could be attributed to humoral factors. In 1979, Janneta and Gendell introduced the concept of neurogenic hypertension caused by pulsatile vascular compression of the left lateral medulla [4]. Animal studies using various models have confirmed the presence of a subpial neuronal group (C-1) in the rostral ventrolateral medulla (RVLM) producing a transient pressor response when stimulated chemically, electrically or mechanically [5–8]. Likewise, there has been an abundance of evidence based upon experimental studies, postmortem anatomic dissections, and radiographic findings to portend that compression of the medulla elicits sympathetically mediated hypertension, even non-pulsatile and regardless of laterality [9]. As a therapeutic intervention, many reports have been published in which the microvascular decompression of the RVLM is associated with a decline in blood pressure of hypertensive patients [4,10]. Also, there have been two reports of resolution of hypertension after posterior fossa decompression for Chiari malformation type I in which the compressive effect of the herniated cerebellar tonsils on the cervicomedullary junction seemed to be the core pathophysiologic process [11,12]. To date, only few cases of arterial hypertension have been published, in which the associated hypertension (HTN) resolved following tumor resection [13]. In the first of such reports, Cameron and Doig reported two cases of cerebellar tumors (hemangioblastoma) with brainstem compression presenting with malignant hypertension [14]. Hedderwick et al. reported a case of hemangioblastoma of the cervicomedullary junction, containing neuropeptide Y in which the associated hypertension abated after tumor resection [15]. However, this marker was not positive in our patient. Approximately

25% of hemangioblastomas are associated with VHL [1]. Our patient did not manifest with retinal and adrenal lesions neither had he high urinary catecholamine excretion precluding the diagnosis of VHL and possible secreting function of the tumor. The older age, and the solitary tumor of cerebellum, along with negative family history for autosomal dominant VHL, all were in favor of the diagnosis of sporadic posterior fossa hemangioblastoma.

Mitigation of arterial hypertension after resection of the tumor in our patient, as well as negative laboratory and imaging studies for secondary causes for HTN supports the proposed mechanism of RVLM compression, as the pathogenesis of HTN.

Conclusion

There had been reports of posterior fossa tumors associated with arterial hypertension. The plausible mechanism of rostral ventrolateral medullary compression is gaining interest as a cause for hypertension. The present case is another clue advocating the proposed mechanism.

List of abbreviations

VHL, von Hippel-Lindau disease; MRI, Magnetic resonance imaging; CT, Computed Tomography; PICA, Posterior inferior cerebellar artery; VMA, Vanillylmandelic acid; EMA, Epithelial membrane antigen; NSE, Neuron Specific Enolase; RVLM, Rostral ventrolateral medulla; HTN, Hypertension.

Consent

Written informed consent was obtained from the patient for publication of this case report and accompanying images. A copy of the written consent is available for review by the Editor-in-Chief of this journal.

Competing interests

The authors declare that they have no competing interests.

Authors' contributions

The authors contributed to surgery and preparation of the manuscript. The primary draft and its final revision was done by ATM. HS was the attendant surgeon and prepared the primary draft and revised the manuscript. MZ aided in surgery and revised the manuscript.
